Perceptual Hash Functions

map visually similar images to similar or identical hash values

Used in:

- content moderation
- copyright protection
- detection of illegal material

Examples:

- pHash
- PDQ
- NeuralHash
- PhotoDNA

Problem

PHFs must satisfy two conflicting properties:

- robustness to small image transformations
- ability to distinguish different images

Hash collisions is when two distinct pieces of data in a hash table share the same hash value.

Collisions enable:

- bypassing moderation systems
- adversarial content injection
- false positives in detection

Project

Project aims to design and implement EvoHash, a framework that utilizes the GigaEvo evolutionary programming system to automatically discover and optimize complex, multi-scale collision attacks.

Objective:

Develop an automated pipeline that evolves attack code to generate target hash collisions for four widely deployed PHF.

PHFs

pHash (Perceptual Hash)

- Converts image to grayscale
- Applies DCT and keeps low-frequency coefficients
- Binarizes coefficients into a hash
- Captures global image structure
- Sensitive to structured / frequency-domain attacks

PDQ

- Resizes and normalizes the image
- Applies DCT-like transform
- Generates a binary hash optimized for Hamming distance
- Robust to resizing, compression, minor edits
- Designed for large-scale matching

PHFs

NeuralHash

Processes image with a neural network
Extracts learned feature representation
Maps features to a compact hash
Robust to complex transformations

Less interpretable than classical methods

PhotoDNA

Not public architecture from Microsoft

Black-box attacks on perceptual hashing systems

1. **Random Noise** — i.i.d. Gaussian perturbations, keep best sample. Minimal robustness baseline.
2. **Sign-SGD family** — estimate gradient via random sampling, update by $\text{sign}(\text{grad})$:
 - a. NES: antithetic pairs $(f(x+\sigma u) - f(x-\sigma u))$ — balanced, low variance
 - b. SimBa: coordinate-wise updates in pixel/DCT space
 - c. ZO-SignSGD: one-sided finite difference $(f(x+\mu u) - f(x))$ — cheaper per query
 - d. ZO-SignSGD v2: central difference + momentum accumulation — smoother convergence
3. **Frequency-domain attacks** — exploit that pHash/PDQ operate in DCT space:
 - a. Prokos: perturbs only low-to-mid DCT frequencies with momentum
 - b. AtkScopes: multi-resolution batched probing in DCT domain
4. **Analytical DCT** — directly manipulates DCT coefficients to flip target hash bits. Exact for pHash/PDQ, inapplicable to neural hashes.

Black-box attacks on perceptual hashing systems

1. **HSJA (HopSkipJump)** — decision-based boundary walk. Starts from a known collision, iteratively steps toward source along the decision boundary, minimizing L2 while preserving collision. Requires an initial adversarial example.
2. **HSJA v2** — self-initializing HSJA: finds starting collision automatically (noise $\rightarrow$ ZO-SignSGD fallback), then boundary walk with adaptive step size.
3. **Two-phase hybrids** — Phase 1: Sign-SGD attack finds collision fast (ignoring L2). Phase 2: HSJA refines it, walking the boundary back toward source to minimize distortion.
 - a. NES + HSJA, SimBa + HSJA, ZO-SignSGD + HSJA — conservative Phase 1 ($\sigma=4$, $lr=2$, 80 iter) with mid-step source shortcuts
 - b. NES + JSHA, SimBa + JSHA, ZO-SignSGD + JSHA — aggressive Phase 1 ($\sigma=80$, $lr=8$, 800 iter), clean handoff to HSJA refinement (25 iter)

Evaluation methods

1. Success

- **ASR (Attack Success Rate):** fraction of image pairs that achieve a hash collision.

2. Distortion

- **Mean L2:** normalized pixel-level perturbation magnitude.
- **LPIPS:** perceptual similarity metric aligned with human vision.

3. Efficiency

- **Efficiency:** $ASR / (\text{mean L2} + \text{coef} * \text{mean LPIPS})$, balancing success and distortion.

4. Practical cost

- **Queries:** number of hash evaluations (black-box cost).
- **Time:** average runtime per attack.

5. Generalization

- **Transferability:** success rate when attacks transfer across different hashing models.

GigaEvo

Enables automated search for PHF collision attacks

Runs the evolutionary loop (generations, selection, mutation)

Each candidate is a Program object (code+metrics+lineage)

Redis-backed storage

Parallel execution: EvolutionEngine + DagRunner

Pipeline of GigaEvo

1. **ValidateCodeStage:** verify code is syntactically valid and passes basic safety checks.
2. **CallProgramFunction:** execute the program's `entrypoint(context)`.
3. **CallValidatorFunction:** run external `validate(context, payload)` on the produced output.
4. **FetchMetrics:** extract the `metrics` dictionary from the validator output.
5. **FetchArtifact:** extract an auxiliary artifact (if the validator returns one).
6. **InsightsStage:** ask the LLM to analyze the current program.
7. **Collector + Lineage Stages:** collect relatives (parents/children) and run LLM analysis of the parent $\rightarrow$ child transition.
8. **MutationContextStage:** build a unified mutation context for the next generation.
9. **EnsureMetricsStage:** normalize metrics into a strict schema and write them back into the `Program`.

Experimental Setup

Models:

- GPT-OSS 120B
- GLM-4.7 Flash
- **Qwen 3.5 122B-A10B**

Dataset:

- 100 Random images pairs from ImageNet Val

Experiment:

- 20 generations of 10 pairs each

Result of evolution for pHash

- Analytical DCT has the best quality among all baseline attacks (and use only 3 queries):

***eff* = 0.022, *L2* = 32.9, *LPIPS* = 0.268**

- During evolution, the analytical attack mutated over 5 generations (crossed with the NES+HSJA hybrid). This has significantly improved the quality (and use only 2 queries):

***eff* = 0.032, *L2* = 22.1, *LPIPS* = 0.183**

Samples for final pHash attack

Deeper analysis of pHash attack

Initial attack

- Fixed margin
- Arbitrary bit processing order
- Only one (analytical) phase of algorithm

Final attack

- Adaptive margin
- Sorting the bits and correcting the worst
- Second phase of boundary walk

Results of evolution for PDQ

- The best baseline for PDQ is NES+HSJA attack (3025 queries):

eff = 0.0225, L2 = 30, LPIPS = 0.289

- On the 2nd generation, LLM invented an analytical DCT attack. By the 7th generation, this attack was crossed with HSJA-based attacks and the best quality was obtained (requires only 119 queries):

eff = 0.0321, L2 = 23.9, LPIPS = 0.146

Deeper analysis of PDQ attack

Initial attack

- Long HSJA phase (15 iterations)
- Black-box NES approach in phase 2

Final attack

- Short HSJA phase (5 iterations)
- Analytical DCT approach in phase 2
- Different techniques for adaptation to image, early termination, bit selection

Attack Transferability

	ASR/L2			
Target Attack	PDQ	pHash	Neural Hash	Photo DNA
PDQ best	 1.00 / 30.5	1.00 / 56.8	1.00 / 71.2	1.00 / 54.9
pHash best	1.00 / 31.0	 1.00 / 22.1	1.00 / 71.1	1.00 / 54.8

Attacks evolved for one PHF tested on all four without retraining

Conclusion

- LLMs can successfully improve existing hash attacks using evolutionary principles in a fairly short time (<10 iterations of evolution)
- High-quality baselines with hyperparameter tuning capabilities/space for implementing improvements are critical to the success of evolution.
- Attacks on NeuralHash/PhotoDNA require much more resources, and perhaps a smarter model for evolution.

Thanks for your attention!
